General Purpose GPU Programming (1)

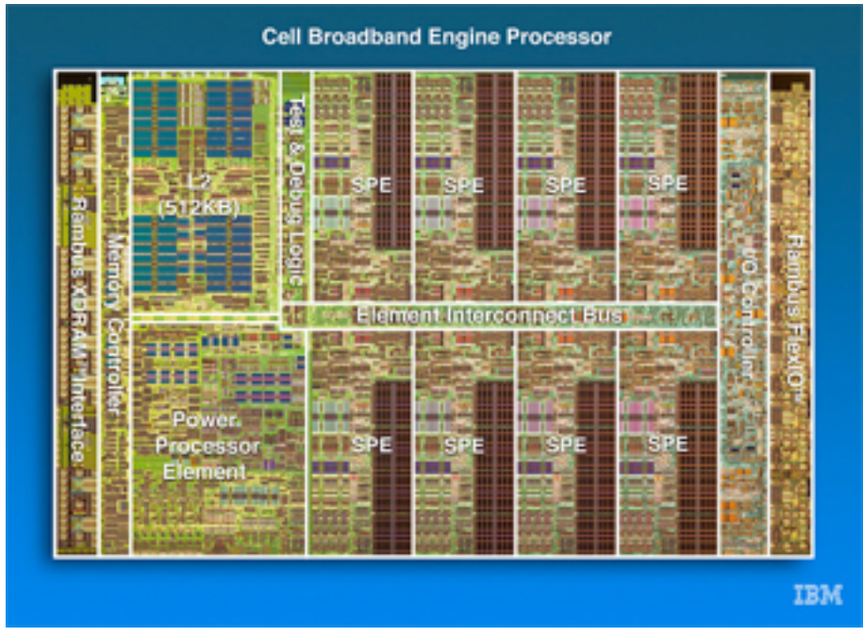

Advanced Operating Systems
Lecture 14

Lecture Outline

- Heterogenous multi-core systems and general purpose GPU programming
- Programming models
  - Heterogenous multi-kernels
  - Main core with heterogenous offload

Heterogeneous Instruction Set Systems

- Increasingly common for a single system to have cores running heterogenous instruction sets
  - CPU + general purpose GPU
  - CPU + offload of TCP, crypto, or multimedia functions
  - Cell processor with PPE + multiple SPE
- Desirable when different instruction sets have radically different performance characteristics
  - GPU hardware does simple SIMD-style computations in parallel at high speed, but performs poorly for code with large numbers of conditional branches
  - A typical CPU is better suited for complex conditional code, but performs poorly with SIMD-style operations
  - Combination of several CPU cores and a GPU is now a ubiquitous system design
  - Other types of heterogeneity are becoming more common as designers try to make better use of the extra transistors which are coming available due to Moore's law

Programming Models

- What programming model to use for systems with heterogenous instruction sets?
  - Radically different cores → radically different programming model?
  - How are cores organised – peers or master/slave architecture?

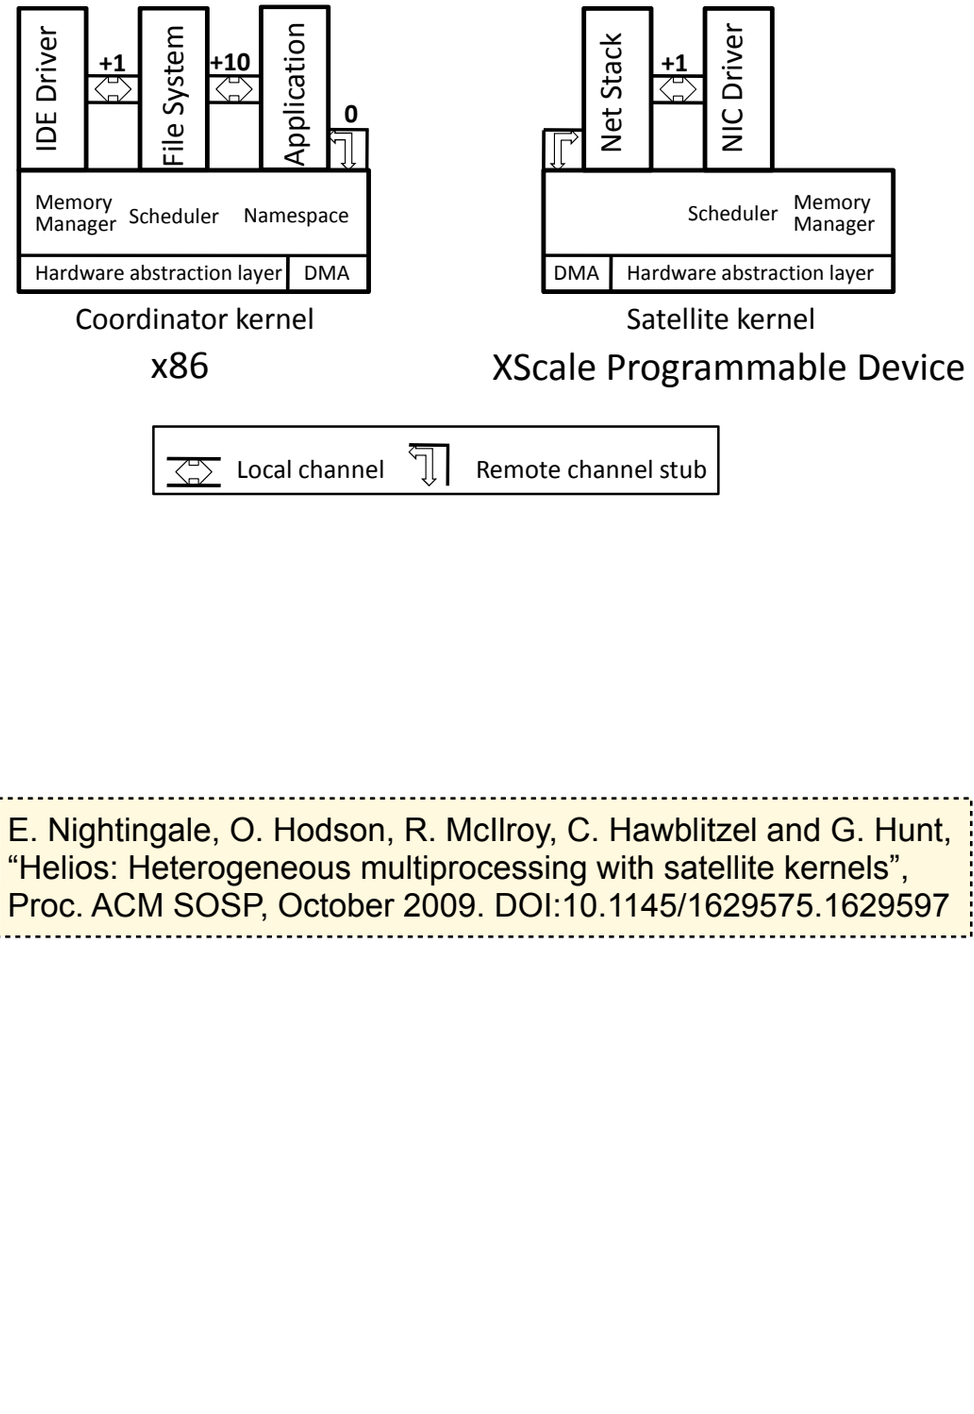

- Three models have been explored:
  - Heterogeneous multi-kernel
  - Main core with heterogenous offload
  - Heterogeneous virtual machines (→ next lecture)

Heterogeneous Multi-kernel Systems

- If cores full-featured, multi-kernel may be suitable
  - Multi-kernel is a message passing distributed system – if messages have a standardised format, processor architecture is unimportant
  - Each core may run a different instruction set, since they don't share data
  - Kernel must be separately compiled for each architecture
  - Applications limited to subset of cores, require compilation as fat binaries, or use JIT compilation
    - May not be possible to effectively balance load across the system, due to limitations where certain processes can execute
    - Performance may suffer if related processes can't be co-located due to resource constraints
- Not widely implemented
  - Systems with multiple full-featured cores generally have homogenous instruction sets

Example: Helios

- A research prototype multi-kernel system designed to exploit heterogenous cores
- Multi-kernel extension to Singularity
  - Runs on x86 NUMA systems, and on x86 systems with offload to an ARM processor on a RAID card
- Some cores types have limited functionality
  - All kernels export the same services; all interactions between tasks, and with kernel, use message-passing
  - Some cores implement certain services by forwarding messages to other cores
- Applications distributed as byte code
  - JIT compilation, as is usual in Singularity
  - Express affinity to other tasks in metadata to allow dynamic load balancing across cores
- Interesting proof-of-concept, but only limited functionality

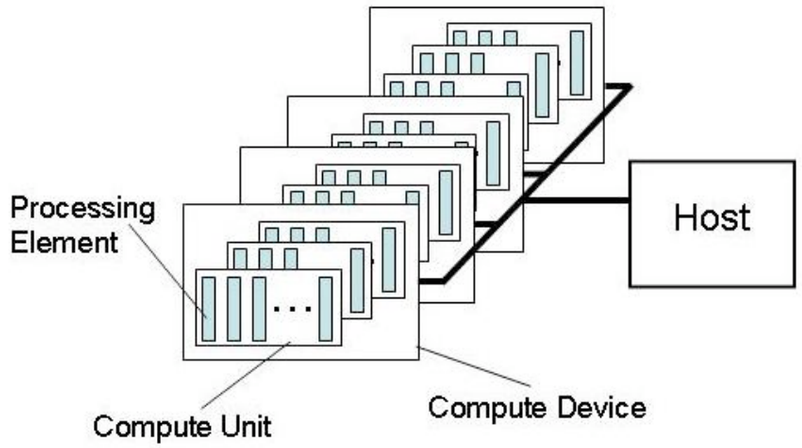

E. Nightingale, O. Hodson, R. McIlroy, C. Hawblitzel and G. Hunt, “Helios: Heterogeneous multiprocessing with satellite kernels”, Proc. ACM SOSP, October 2009. DOI:10.1145/1629575.1629597

Main Core With Heterogeneous Offload

- Typical modern hardware architecture:
  - Several full-featured main processor cores, with a common instruction set, run the main operating system
  - Specialised, limited functionality, processors support the main cores, with functions being offloaded from the main cores as appropriate
    - These processors typically have radically different instruction set and/or programming model to the main processor cores
    - Example: a multicore CPU with offload of graphics to a separate GPU
- Implications for operating system design:
  - Programming model for offload processors differs from the main cores
    - Typically not sufficient to run a full operating system
    - May be too limited to support a standard programming language
  - Offload processors don’t run independently – they’re resources invoked by the master CPU (e.g., for graphics, network stack, or crypto offload)

Graphics Offload Hardware

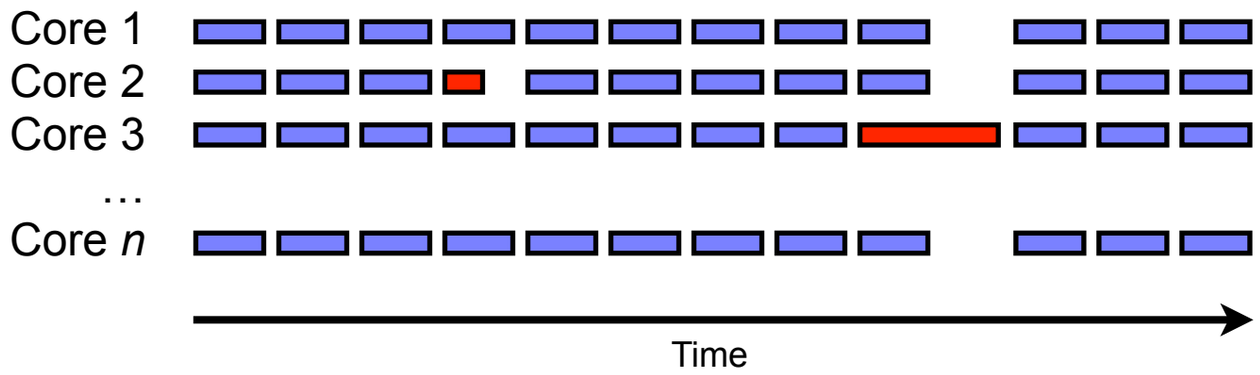

- A ubiquitous offload model is for graphics: general purpose GPU programming
- Offload processors are GPU devices – a large grid of compute cores designed for SIMD-style array processing
  - Thousands of cores available on modern GPUs
  - Very high sequential memory bandwidth – designed for array processing, with limited support for pointers and arbitrary memory access
  - Weak support for conditional branches – the model is that each core runs the same code on different data → SIMD processing
  - No access to I/O devices other than the screen; interactions with the rest of the system via block DMA transfers
- Parallel SIMD programming model makes such cores unsuitable for general-purpose programming languages
  - Cannot effectively run general purpose software

[Source: The OpenCL specification, v1.0]

Programming Model

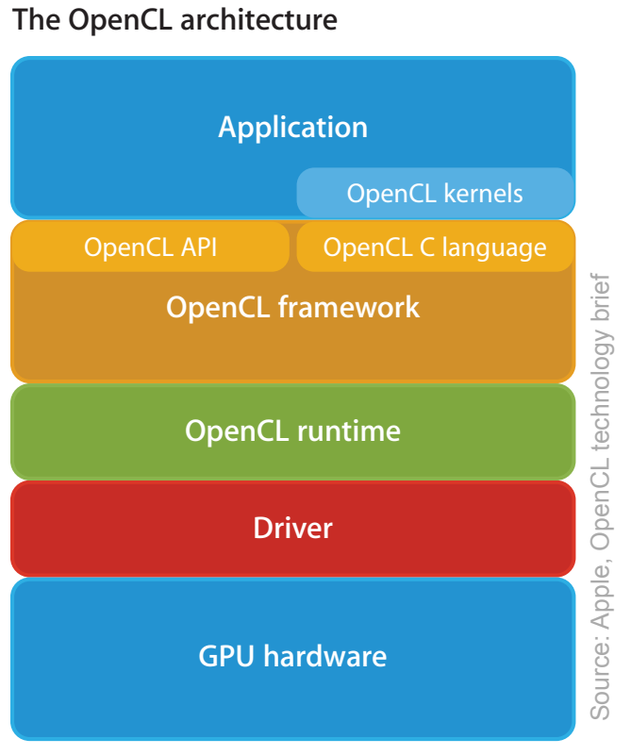

- Use multiple threads rather than loops
  - Operate on entire arrays in parallel, rather than iterating over elements
  - Threads may run in lock-step across thousands of cores – a branch may disrupt execution across threads if it increases execution time

  - Designed for batch array processing – “general purpose” implies flexibility in how each element is processed
- Task scheduler on offload processor assigns work
  - Implicit parallelism – programmers write *kernel function*, system parallelises

Example: OpenCL (1)

- An open, vendor neutral, standard for programming general purpose GPU offload devices
  - http://www.khronos.org/opencl/
- General purpose GPU code is written in OpenCL C
  - An extended subset of ISO C99
  - Adds built-in vector, 2D, and 3D image types
  - Adds pointer qualifiers to reference host and GPU memory; use of pointers restricted since memory is not shared between host and device (explicitly copy inputs and outputs to/from device)
  - Very restricted standard library
  - Defines the concept of a *kernel function* that can be JIT compiled and executed on a device
- OpenCL framework provides JIT compilation and device management
- OpenCL runtime manages execution of code as a large number of threads, running kernel functions on different parts of the data

Example: OpenCL (2)

```
void
trad_mul(int n,
         const float *a,
         const float *b,
         float *c)
{
  int i;
  for (i=0; i<n; i++)
    c[i] = a[i] * b[i];
}
```

```
kernel void
dp_mul(global const float *a,
       global const float *b,
       global float *c)
{
  int id = get_global_id(0);

  c[id] = a[id] * b[id];

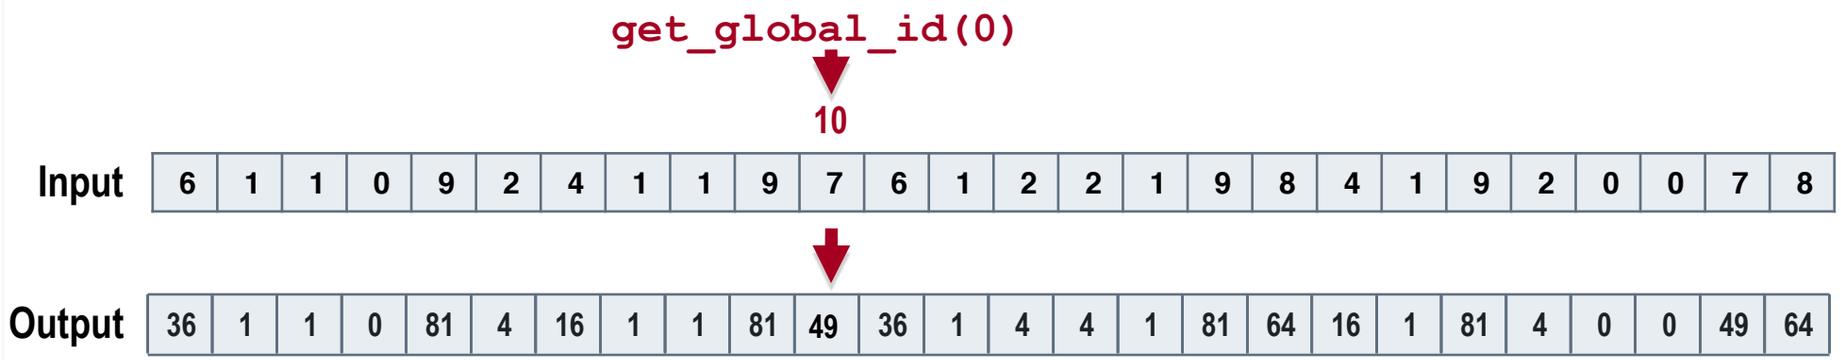

} // execute over "n" work-items
```

Source: Khronos Group, OpenCL Overview

- Main component of OpenCL C programs: kernel functions executed on device
  - The **`global`** qualifier on pointers specifies memory region on which they operate
  - The **`get_global_id(…)`** API function identifies work item currently being processed by this kernel
- Groups of kernel functions are queued to operate on offload device
  - Kernel functions JIT-compiled and code cached when queued for execution
  - Sizes of vectors and arrays on which they operate specified when enqueueing work
  - Execution of kernels is parallel and asynchronous to main processors
- Complex low-level API provided for querying device capabilities, offloading work onto the device

Example: OpenCL (3)

```
kernel void square(global float* input, global float* output)
{
  int i = get_global_id(0);
  output[i] = input[i] * input[i];
}
```

Source: Khronos Group, OpenCL Overview

- Extended subset of C is familiar for programmers
- A cleaner model might be a purely functional language, with built-in array and vector types
  - Explicitly operate on arrays, with compiler implicitly deriving kernel functions
  - Rather than explicitly operating on kernel functions, with array dimensions defined to runtime library implicitly via OpenCL API calls

Integration With Main Operating System

- Host operating system manages offload hardware
  - Responsible for loading code onto the offload device
  - Responsible for scheduling execution of code on the offload device
  - Offload devices do not run an OS – they're dumb devices, managed by a device driver

- Low-level API and programming model
  - High conceptual burden to use
  - Cannot run general purpose code; programming and communications model is too restricted
  - Does not easily integrate with host applications – too much boilerplate

Discussion and Further Reading

- Ofer Rosenberg, “OpenCL Overview”, Khronos Group, November 2011. http://www.khronos.org/assets/uploads/developers/library/overview/opencl-overview.pdf

- Complexity versus performance trade-off in OpenCL – how much does this limit usefulness?
- How might SIMD-style processing be more cleanly incorporated into modern languages?
